We develop the first algorithmic approach to compute provably good ordering policies for a multiperiod, capacitated, stochastic inventory system facing stochastic nonstationary and correlated demands that evolve over time. Our approach is computationally efficient and guaranteed to produce a policy with total expected cost no more than twice that of an optimal policy. As part of our computational approach, we propose a novel scheme to account for backlogging costs in a capacitated, multiperiod environment. Our cost-accounting scheme, called the forced marginal backlogging cost-accounting scheme, is significantly different from the period-by-period accounting approach to backlogging costs used in dynamic programming; it captures the long-term impact of a decision on system performance in the presence of capacity constraints. In the likely event that the per-unit order costs are large compared to the holding and backlogging costs, a transformation of cost parameters yields a significantly improved guarantee. We also introduce new semimyopic policies based on our new cost-accounting scheme to derive bounds on the optimal base-stock levels. We show that these bounds can be used to effectively improve any policy. Finally, empirical evidence is presented that indicates that the typical performance of this approach is significantly stronger than these worst-case guarantees.

Subject classifications: stochastic inventory control; heuristics; approximation algorithms.

Area of review: Manufacturing, Service, and Supply Chain Operations.

1. Introduction

The periodic-review, capacitated inventory control problem for systems facing stochastic, nonstationary (time-dependent) demands that are correlated and evolve over time is an important classical problem that is widely recognized to be computationally challenging. We develop a new algorithmic approach to compute the order quantity for such a system. We build on the work of Levi et al. (2007), who used a marginal holding cost accounting scheme and cost-balancing techniques to derive the first policies with worst-case performance guarantees for uncapacitated models. In this paper, we introduce a novel marginal backlogging cost-accounting scheme that, in combination with their techniques, leads to analogous results for the much-harder capacitated model. We believe that our new cost-accounting scheme will have applications in many other settings. Our algorithm is guaranteed to compute a solution of total expected cost of no more than twice that of an optimal policy for any instance of the problem. The algorithm is computationally efficient and implementable without having to exhaustively enumerate future scenarios and corresponding future decisions. In particular, the decision made in the current period is unaffected by any future decision. Thus, it can be implemented efficiently even in the presence of complex demand structures.

Specifically, we consider single-item models with one location and a finite planning horizon of $T$ discrete time periods. The demands over the $T$ periods are random variables that can be nonstationary and correlated. The costs consist of a per-unit, time-dependent ordering cost, a per-unit holding cost for carrying excess inventory from period to period, and a per-unit backlogging cost, which is a penalty incurred, in each period, for each unit of unsatisfied demand (where all shortages are fully backlogged). There is a time-dependent capacity constraint on the number of
units ordered in each period and a lead time between the time that an order is placed and the time that it actually arrives. The capacity constraints and lead times may be stochastic.

Capacitated problems are inherently more difficult computationally compared to their uncapacitated counterparts. The constraint on capacity makes future costs heavily dependent on current decisions. Myopic policies, which do not consider the impact of a decision made in the current period on the costs incurred in future periods, seem to perform well for some scenarios in uncapacitated systems and are even optimal in some settings (see Veinott 1965, Ignall and Veinott 1969, Iida and Zipkin 2006, Lu et al. 2006). However, when applied to capacitated problems, they usually perform very poorly because they do not consider possible capacity limitations in future periods.

In this work, we introduce a look-ahead backlogging cost-accounting scheme, called the forced marginal backlogging cost-accounting scheme, to capture the long-term impact of current decisions on future costs in the presence of capacity constraints. Our new cost-accounting scheme assigns to the decision in each period all of the expected backorder costs that, once this decision is made, become inevitable; that is, they are unaffected by any decision made in future periods, and are dependent only on future demands. The forced marginal backlogging cost reduces to the traditional backlogging cost when the capacity is infinite; thus, it is a generalization of the traditional backlogging cost. Finally, as discussed in §3.1, it is straightforward to compute in most common scenarios.

The key feature distinguishing the algorithms presented in this paper from those previously studied for capacitated systems is the treatment of correlation in demand across time, as well as nonstationarity. Moreover, we allow observations of the past to change demand forecasts for the future. Our model also captures other important characteristics of a nonstationary environment: the parameters are fully time dependent, including cost parameters and system capacity. An important application of demand correlation and nonstationarity is in the use of dynamic demand forecasts. These forecasts and the way they evolve over time provide vital information that can be used to find effective inventory control policies in dynamic and highly volatile demand environments. The assumptions that we make on the demand distributions in this work are mild enough to generalize all of the currently known approaches in the literature to model correlation and nonstationarity of demand over time. These include classical approaches such as the martingale model of forecast evolution (MMFE), exogenous Markovian demand, time series, order-one auto-regressive demand, and random walks. For an overview of the different approaches and models, and for relevant references, we refer the reader to Iida and Zipkin (2006) and Dong and Lee (2003) and Özer and Wei (2004).

High correlation between demands across different periods in nonstationary and dynamic environments presents a considerable challenge to computing, or even approximating, optimal inventory control policies. The dominant paradigm in almost all of the existing literature has been to formulate multiperiod capacitated models using dynamic programming. The optimization problem is defined recursively over time by using subproblems for each possible state of the system. The state usually consists of a given time period, the level of inventory at the beginning of the period, the resulting conditional distribution of future demands over the rest of the horizon, and possibly more information that is available by that period. For each subproblem, an optimal solution is computed to minimize the expected overall discounted cost from the current point to the end of the horizon. This framework has turned out to be very effective in characterizing the structure of the optimal policy of the overall system. Assuming stationary linear costs and independent and identically distributed (i.i.d.) demands, Federgruen and Zipkin (1986a, b) showed that a modified, base-stock policy is optimal under infinite-horizon average cost and discounted cost criteria. They established the existence of a target inventory level such that the optimal policy aims to keep inventory levels as close as possible to that target. When the inventory level at the beginning of the period is above the target level, the optimal policy does not order. When the inventory level at the beginning of the period is below the target level, it might not be possible to order up to the target level because of the capacity constraint. In this case, the order placed would be up to capacity. Tayur (1992), Kapuscinski and Tayur (1998), and Aviv and Federgruen (1997) derived the optimal policy in the same settings, but for independent cyclical demands. More recently, Özer and Wei (2004) showed the optimality of modified base-stock policies in single-item periodic-reviewed capacitated inventory control models with advance demand information.

Áxsäter (1990) is the first to introduce the notion of matching between pairs of demand and supply units. Specifically, he observes that in a distribution system with a single depot and multiple retailers, a supply unit ordered by a retailer can be used to fill a corresponding demand unit following a certain order. He matches this pair of units and evaluates the corresponding expected holding cost. Katircioglu and Atkins (1996) have used this observation to analyze the optimal policies in unit demand inventory systems. For the uncapacitated periodic-review stochastic inventory control problem, Muharremoglu and Tsitsiklis (2008) have proposed an alternative approach to the dynamic programming framework. They have observed that this problem can be decoupled into a series of unit supply-demand subproblems, where each subproblem corresponds to a single unit of supply and a single unit of demand that are matched. This novel approach enabled them to substantially simplify some of the dynamic-programming-based proofs on the structure of optimal policies, as well as to prove several important new structural results. In
particular, they have established the optimality of state-dependent base-stock policies for the uncapacitated model with general Markov-modulated demand. Using this unit decomposition, they have also suggested new methods to compute the optimal policies. However, their computational methods are essentially dynamic programming approaches applied to the unit subproblems; hence, they suffer from similar problems in the presence of correlated and non-stationary demand. Although our approach is very different from theirs, we use some of their ideas as technical tools in some of the proofs. Janakiraman and Muckstadt (2003) have extended this approach to capacitated models and established the optimality of state-dependent modified base-stock policies for models with Markov-modulated demand.

Unfortunately, the rather simple forms of these policies do not always lead to efficient algorithms for computing the optimal policies. Complex demand structures, such as the one we consider in this work, cause the state space of the corresponding dynamic programs to explode (see Iida and Zipkin 2006, Dong and Lee 2003 for relevant discussions on the MMFE model). There does not exist at present, nor is there likely to be developed, an efficient algorithm to solve these dynamic programs to optimality, even for the uncapacitated model. The difficulty comes from the fact that we need to solve “too many” subproblems, a phenomenon known as the curse of dimensionality. To date, computational procedures have been made tractable only under assumptions of simple demand structures. If the demands in different periods are independent, the corresponding dynamic programs are relatively straightforward to solve. Dynamic programming can still be tractable for uncapacitated models with Markov-modulated demand, but under rather strong assumptions on the structure and the size of the state space of the underlying Markov process (see, for example, Song and Zipkin 1993, Chen and Song 2001). Tayur (1992) uses the shortfall distribution and the theory of storage processes to derive an efficient computational method for computing the optimal policy in the stationary cost, i.i.d. demand, average cost case. Roundy and Muckstadt (2000) showed how to obtain approximate base-stock levels, also for the stationary cost and i.i.d. demand case, by approximating the distribution of the shortfall process. Kapuscinski and Tayur (1998) proposed a simulation-based technique using infinitesimal perturbation analysis to compute the optimal policy for capacitated problems with independent, cyclical demands. Finally, Özer and Wei (2004) developed an exact dynamic programming approach for the model with advance demand information when the forecast horizon exceeds the lead time by two periods, and so the state space is only two dimensional.

There have been heuristic approaches to compute order quantities for capacitated problems. However, we are aware of very few attempts to analyze the worst-case performance of heuristics and most bounds derived are dependent on the particular input (see, for example, Lu et al. 2006). To the best of our knowledge, there are no other policies for stochastic inventory control models with constant worst-case performance guarantees. Metters (1997) found heuristics for capacitated, lost-sales problems with independent, cyclical demands. Chan (1999) have considered heuristics for uncapacitated and capacitated multi-item models. Instead of solving the one-period problem (as in the myopic policy), they have added a penalty function to the one-period problem, which they called the Q-function. This function accounts for the holding cost incurred by the inventory left at the end of the period over the entire horizon. Their look-ahead approach with respect to the holding cost is somewhat related to our approach, although significantly different.

As we have already mentioned, this paper builds on the work of Levi et al. (2007). They give the first algorithms with a constant performance guarantee for the uncapacitated stochastic inventory control model with correlated, non-stationary demands; specifically, their algorithms always find solutions of total expected cost no more than twice the optimal. Their algorithms are based on two main ideas. First, they construct a look-ahead holding-cost accounting scheme, called the marginal holding-cost accounting scheme, to compute the additional holding costs incurred by units ordered in the current period throughout the entire horizon. Second, they use cost-balancing techniques in that, in each period, they order exactly to balance the following two opposing costs: the conditional expected marginal holding cost against the conditional expected period backlogging cost a lead time ahead. Their approach relies heavily on the ability of the system to order in each period a “balancing quantity” that equalizes the expected marginal holding cost and the expected backlogging cost in the period. In capacitated systems, the approach fails because this balancing quantity might not be attainable due to capacity constraints. Our forced marginal backlogging cost-accounting scheme is designed to remedy this problem by reassigning backlogging costs more appropriately to the decisions that create them, enabling us to find a “balancing order quantity” for capacitated systems. Suppose that in the current period the order placed was not up to capacity; we wish to account for the potential backlogging cost in future periods incurred directly by the decision not to use the full available capacity. Assume temporarily that we order up to capacity in each one of the periods. Suppose now that in the current period we do not order up to capacity. Then, the expected marginal backlogging cost associated with the current period is the overall increase in the expected backlogging cost over the entire horizon resulting from this decision. In this way, our balancing policy for a capacitated system is able to achieve the same worst-case performance guarantee of two, with surprisingly little additional computational effort. When applied to uncapacitated models, the policies described in this paper are identical to the dual-balancing policies described by
Levi et al. (2007). Thus, they can be viewed as generalizations of the original dual-balancing policies to capacitated inventory models.

We also use the marginal holding and forced marginal backlogging cost-accounting schemes to derive additional semimyopic policies called the lower-myopic and upper-myopic policies. The policies provide lower and upper bounds on the optimal base-stock levels, respectively, that can be used in conjunction with any policy to achieve lower expected cost.

Furthermore, in §4.2 we show how to use standard cost transformations to improve the performance of the algorithms in many important settings (see also Levi et al. 2007). These transformations yield a modified instance of the problem that is equivalent to the original one from an optimization perspective, but models only holding and backlogging costs. If the per-unit ordering cost is constant over time, then applying our algorithms to the modified instance yields an approximation algorithm with a worst-case guarantee of two with respect to the holding and backlogging costs, and which has the same total per-unit ordering cost as the optimal policy. More generally, when the ordering costs are large, the worst-case performance guarantee of the modified cost dual-balancing policy will be much better than two.

In §6, we test the typical empirical performance of the balancing algorithms in two settings. We consider an inventory system that has i.i.d. demand (no correlations), and a demand distribution with an exponential tail, because the optimal policy can be computed analytically. (The motivation is to test the balancing policies at least in one environment, in which the optimal policy and cost are known.) However, balancing policies are most attractive in scenarios with complex demand structures, whereas optimal policies cannot be computed and no provably good heuristics or reasonable lower bounds are known. Thus, we also consider the same set of test scenarios tested in Hurley et al. (2006), in which the uncapped versions of these algorithms were evaluated computationally. In these scenarios, the demands and forecasts evolve according to the multiplicative MMFE model. Optimal policies are not computable, and strong lower bounds on the optimal cost do not exist, so we used the myopic policy as a benchmark for evaluating performance. The performance of the balancing policies is very robust. It was within 11% of optimal, on average, in the first test (always within 25%), and consistently improved upon myopic by over 27%, on average, in the first test (always within 25%), and consistently improved upon myopic by over 50% in many scenarios.

This paper is organized as follows. In §2, we present the mathematical formulation of the periodic-review, capacitated, stochastic inventory control problem. In §3, we describe the forced marginal backlogging cost-accounting scheme for the capacitated model. In §4, we describe the balancing policy and its worst-case analysis. We also extend the approximation results to the case of discrete demand and stochastic lead times (see Appendix C in the online appendices, which are available as part of the online version that can be found at http://or.pubs.informs.org/). In §5, we develop lower and upper bounds on the optimal inventory levels, and show how to use them to improve any policy. Section 6 contains our computational results. Online Appendix A contains a very simple, illustrative example for the case of integer-valued demand. In Online Appendix B, we present a detailed description of the scenarios tested in the computational results.

2. Capacitated Periodic-Review Stochastic Inventory Control Problem

In this section, we provide the mathematical formulation of the capacitated periodic-review stochastic inventory problem and introduce some of the notation used throughout the paper. As a general convention, we distinguish between a random variable and its realization using capital letters and lower-case letters, respectively. Script font is used to denote sets. We consider a finite planning horizon of $T$ periods numbered $t = 1, \ldots, T$ (note that $t$ and $T$ are both deterministic, unlike the convention above). The demands over these periods are random variables, denoted by $D_1, \ldots, D_T$.

As part of the model, we assume that at the beginning of each period $s$ we are given what we call an information set that is denoted by $\mathcal{F}_s$. The information set $\mathcal{F}_s$ contains all of the information that is available at the beginning of time period $s$. More specifically, the information set $\mathcal{F}_s$ consists of the realized demands $(d_1, \ldots, d_{s-1})$ over the interval $[1, s)$, and possibly some more (external) information denoted by $(w_1, \ldots, w_s)$. The information set $\mathcal{F}_s$ in period $s$ is one specific realization in the set of all possible realizations of the random vector $F_s = (D_1, \ldots, D_s, W_1, \ldots, W_s)$. This set is denoted by $\mathcal{F}_s$. In addition, we assume that in each period $s$ there is a known conditional joint distribution of the future demands $(D_{s+1}, \ldots, D_T)$, denoted by $I_s := I_s(f_s)$, which is determined by $f_s$ (i.e., knowing $f_s$, we also know $I_s(f_s)$). For ease of notation, $D_t$ will always denote the random demand in period $t$ according to the conditional joint distribution $I_s$ for some $s \leq t$, where it will be clear from the context to which period $s$ we refer. We will use $t$ as the general index for time, and $s$ will always refer to the current period. The only assumption on the demands is that for each $s = 1, \ldots, T$, and each $f_s \in \mathcal{F}_s$, the conditional expectation $E[D_t | f_s]$ is well defined and finite for each period $t \geq s$. In particular, we allow nonstationarity and correlation between the demands of different periods.

In the periodic-review stochastic inventory control problem, our goal is to supply each unit of demand while attempting to avoid ordering it either too early or too late. In period $t$ ($t = 1, \ldots, T$), three types of costs are incurred, a per-unit ordering cost $c_t$ for ordering up to $u_t$ units, where $u_t \geq 0$ is the available order capacity in period $t$; a per-unit holding cost $h_t$ for holding excess inventory from period $t$ to $t + 1$; and a per-unit backlogging penalty $p_t$, ...
that is incurred for each unsatisfied unit of demand at the end of period \( t \). Unsatisfied units of demand are usually called backorders. Backorders accumulate fully over time until they are satisfied. That is, each unit of unsatisfied demand will stay in the system and will incur a backlogging penalty in each period until it is satisfied. In addition, there is a lead time of \( L \) periods between the time an order is placed and the time at which it actually arrives. We first assume that the lead time is a known integer \( L \). In Online Appendix C, we show that our policy can be modified to handle stochastic lead times under the assumption of no order crossing (i.e., any order arrives no later than those placed later in time). In §4.1, we show that extensions to the case of random capacities are straightforward.

There is also a discount factor \( \alpha \leq 1 \). The cost incurred in period \( t \) is discounted by a factor of \( \alpha^t \). Because the horizon is finite and the cost parameters are time-dependent, we can assume without loss of generality that \( \alpha = 1 \). We also assume that there is no speculative motivation for holding inventory or having backorders in the system. To enforce this, we assume that for each \( t = 2, \ldots, T - L \), the inequalities \( c_t \leq c_{t-1} + h_{t+L-1} \) and \( c_t \leq c_{t-1} + p_{t+L} \) are maintained (where \( c_{t+L} = 0 \)). If there is a discount factor, we require that \( \alpha c_t \leq c_{t-1} + \alpha h_{t+L-1} \) and \( c_t \leq \alpha c_{t-1} + \alpha^t p_{t+L} \). We also assume that the parameters \( h_t \), \( p_t \), and \( c_t \) are all nonnegative. Note that the parameters \( h_t \) and \( p_t \) can be defined to take care of excess inventory and backorders at the end of the planning horizon. In particular, \( p_t \) can be set sufficiently high so as to ensure that there are very few backorders at the end of period \( T \).

The goal is to find a feasible ordering policy (i.e., one that respects the capacity constraints) that minimizes the overall expected discounted ordering cost, holding cost, and backlogging cost. We consider only policies that are nonanticipatory, i.e., at time \( s \), the information that a feasible policy can use consists only of \( f_s \) and the current inventory level.

Throughout the paper, we will use \( D_{[s]} \) to denote the accumulated demand over the interval \([s, T]\), i.e., \( D_{[s]} := \sum_{j=s}^{T} D_j \). We will also use superscripts \( P \) and OPT to refer to a given policy \( P \) and an optimal policy, respectively.

Given a feasible policy \( P \), we describe the dynamics of the system using the following terminology. We let \( N_t \) denote the net inventory at the end of period \( t \), which can be either positive (in the presence of physical on-hand inventory) or negative (in the presence of backorders). Because we consider a lead time of \( L \) periods, we also consider the orders that are on the way. The sum of the units included in these orders, added to the current net inventory, is referred to as the inventory position of the system. We let \( X_t \) be the inventory position at the beginning of period \( t \). If the order in period \( t \) is placed, i.e., \( X_t := N_{t-1} + \sum_{j=t-L}^{t-1} Q_j \) (for \( t = 1, \ldots, T \)), where \( Q_j \) denotes the number of units ordered in period \( j \) (we will sometimes denote \( \sum_{j=t-L}^{t-1} Q_j \) by \( Q_{[t-L, t-1]} \)). Similarly, we let \( Y_t \) be the inventory position after the order in period \( t \) is placed, i.e., \( Y_t = X_t + Q_t \).

Note that once we know the policy \( P \) and the information set \( f_s \in \mathcal{F}_s \), we can easily compute \( n_{s-1}, x_s, \) and \( y_s \), where again these are the realizations of \( N_{s-1}, X_s, \) and \( Y_s \), respectively.

### 3. Marginal Cost Accounting Scheme

In this section, we present a marginal cost accounting scheme for stochastic inventory control problems with capacity constraints on the size of the order in each period. This extends and generalizes the marginal cost accounting discussed by Levi et al. (2007). Because this cost-accounting approach is central for our approximation results, we explain it in detail, repeating some of the ideas of that paper. Our approach differs significantly from the traditional cost-accounting approaches, which are based on standard dynamic programming.

We start by reviewing their cost-accounting approach, which is called marginal cost accounting. The main idea underlying this approach is to account for all the expected costs associated with the decision of how many units to order in period \( t \) when this decision is made. More specifically, the decision in period \( t \) is associated with all the expected costs that, after that decision is made, become unaffected by any future decision, and are only dependent on future demands. In Levi et al. (2007), it was shown that in uncapacitated models, these costs are relatively easy to compute already in period \( t \), even though they may include costs that are going to be incurred only in future periods.

Taking this approach, Levi et al. have proposed a marginal holding-cost accounting scheme. Their approach is based on the convention that units in inventory are consumed on a first-ordered-first-consumed basis. This implies that the overall holding cost of the \( q_s \) units ordered in period \( s \) (i.e., the holding cost they incur over the entire horizon \([s, T]\)) is a function only of future demands, and is independent of any future decision. Based on the assumption that inventory is consumed on a first-ordered-first-consumed basis, the \( q_s \) units on order will be used to satisfy demand only when the \( x_s \) units presently in the system have been completely consumed. Among these \( q_s \) units, the number of those still remaining in inventory at the end of period \( j \) (where \( j \geq s + L \)) is precisely \( (q_s - (D_{[s+L]} - x_s)^+) \). Each of these units incurs a cost of \( h_j \). More specifically, conditioning on an information set \( f_s \in \mathcal{F}_s \), the marginal holding cost is defined to be (assuming again that \( \alpha = 1 \)) \( \sum_{j=s+L}^{T} h_j (q_s - (D_{[s+L]} - x_s)^+) \). Observe again that for each nonanticipatory policy \( P \), if conditioned on some \( f_s \in \mathcal{F}_s \), the inventory position at the beginning of period \( t \), denoted by \( x_s^P \), is known deterministically. In addition, once the order in period \( s \) is determined, the backlogging cost a lead time ahead in period \( s + L \), i.e., \( p_{s+L} (D_{[s+L]} - x_s^P)^+ \), is also dependent only on the future demands. This leads to a marginal cost accounting.

For each feasible policy \( P \), let \( H_s^P \) be the ordering and holding cost incurred over the interval \([t, T]\) by the \( Q_t^P \).
units ordered in period \( t \) (for \( t = 1, \ldots, T \)), and let \( \Pi_t^P \) be the backlogging cost incurred a lead time ahead in period \( t + L \) (\( t = 1 - L, \ldots, T - L \)). That is, \( H_t^P = c_t Q_t^P + \sum_{j=t+1}^{t+L} h_j (Q_j^P - (D_j - X_j^P)^+) \) and \( H_t^P := p_{t+L}(D_{t+L} - (X_{t+L}^P + Q_t^P)^+) \) (where \( D_j := d_j \) with probability one and \( Q_t^P = q_t \) is given as an input, for each \( j \leq 0 \)). Let \( \mathcal{C}(P) \) be the cost of the policy \( P \). Clearly,

\[
\mathcal{C}(P) := \sum_{t=1}^{T-L} \Pi_t^P + H_{(-\infty,T]} + \sum_{t=1}^{T-L} (H_t^P + \Pi_t^P),
\]

where \( H_{(-\infty,T]} \) denotes the total expected holding cost incurred over the interval \([1, T]\) by units ordered before period 1. We note that the first two expressions \( \sum_{t=1}^{T-L} \Pi_t^P \) and \( H_{(-\infty,T]} \) are not affected by our decisions (i.e., they are the same for any feasible policy and each realization of the demands). Note that, without loss of generality, we can assume that \( Q_t^P = H_t^P = 0 \) for any policy \( P \) and each period \( t = T - L + 1, \ldots, T \), because nothing that is ordered in these periods can be used within the given planning horizon.

In models with no capacity constraints, there is a fundamental difference between holding cost and backlogging cost. In particular, any mistake of ordering “too little” can be fixed in the next period to avoid further backlogging cost. In particular, the decision of how many units to order in period \( t \) only accounts for costs incurred in a single period. Moreover, the effect of this decision, if we have ordered too much,” may last for a number of periods depending on the realized future demands. That is, no future decision can fix this mistake because we cannot order a negative quantity. Consequently, \( \Pi_t^P \) only accounts for costs incurred in a single period, namely, backlogging cost in period \( t + L \), and \( H_t^P \) accounts for holding costs incurred over multiple periods.

By way of contrast, in models with capacity constraints on the size of the order in each period, the above observation is no longer valid. More specifically, because of the capacity constraints, it is no longer true that a mistake of ordering “too little” in the current expected period can always be fixed by decisions made in future periods.

### 3.1. Marginal Backlogging Cost Accounting

We now present a new backlogging cost accounting that associates with the decision of how many units to order in period \( s \) what we shall call forced backlogging cost resulting from this decision in future periods.

Consider some period \( s \). Suppose that \( x_s \) is the inventory position at the beginning of period \( s \) and that the number of units ordered in the period is \( q_s < u_s \). Let \( \tilde{q}_s \) be the resulting unused slack capacity in period \( s \), i.e., \( \tilde{q}_s = u_s - q_s > 0 \). Focus now on some future period \( t \geq s + L \) when this order arrives and becomes available. Suppose that for some realization of the demands, we have that \( d_{[t]} - (x_s + q_s + \sum_{j \in [s,t-L]} u_j) > 0 \). This implies that there exists a shortage in period \( t \), and moreover, even if in every period after period \( s \) and until period \( t - L \) the orders had been up to the maximum available capacity, this part of the shortage in period \( t \) would still exist and incur the corresponding backlogging cost. The actual shortage may be even bigger and equal to \( d_{[t]} - (x_s + q_s + \sum_{j \in [s,t-L]} u_j) > 0 \) (recall that \( q_s < u_s \) for each period \( j \)). In other words, given our decision in period \( s \), this part of the shortage could not be avoided by any decision made over the interval \([s, t - L]\) (clearly, any order placed after period \( t - L \) will not be available by time \( t \)). We conclude that if more units had been ordered in period \( s \), then at least some of the shortage in period \( t \) could have been avoided. More precisely, the maximum number of units of shortage that could have been avoided by ordering more units in period \( s \) is equal to \( \min\{\tilde{q}_s, (d_{[t]} - (x_s + q_s + \sum_{j \in [s,t-L]} u_j))^+\} \). The intuition is that by ordering more units in period \( s \), we could have averted part of the shortage in period \( t \), but clearly not more than the unused slack capacity \( \tilde{q}_s \) because we could not have ordered in period \( s \) more than additional \( \tilde{q}_s \) units. In this case, we would say that this part of the backlogging cost in period \( t \) was forced by the decision in period \( s \), and hence period \( s \) is associated with a backlogging penalty of \( p_s \min\{\tilde{q}_s, (d_{[t]} - (x_s + q_s + \sum_{j \in [s,t-L]} u_j))^+\} \). This is significantly different from the traditional backlogging cost accounting, in which this cost would be associated with period \( t - L \).

Let \( W_s \) be the shortage in period \( t \) that is forced by the decision in period \( s \) (where again \( s \leq t - L \)), i.e.,

\[
W_s := \min\left\{ \tilde{q}_s, \left( D_{[s,t]} - \left( X_s + Q_s + \sum_{j \in [s,t-L]} u_j \right) \right)^+ \right\}.
\]

An alternative way to express \( W_s \), using \( \min(a, (b)^+) = (b)^+ - (b - a)^+ \) for \( a \in \mathbb{R} \) and \( b \in \mathbb{R} \), is

\[
W_s := \left( D_{[s,t]} - \left( X_s + Q_s + \sum_{j \in [s,t-L]} u_j \right) \right)^+ - \left( D_{[s,t]} - \left( X_s + \sum_{j \in [s,t-L]} u_j \right) \right)^+.
\]

Now using the equalities, \( NI_s = X_s + Q_s + \sum_{j \in [s,t-L]} Q_j - D_{[s,t]} \) (for each \( s \leq t - L \)) and \( u_j = Q_j + \tilde{Q}_j \) (for each \( j = s, \ldots, t - L \)), we conclude that Equation (2) can be written as

\[
\left( D_t - NI_s - \sum_{j \in [s,t-L]} \tilde{Q}_j \right)^+ - \left( D_t - NI_s - \sum_{j \in [s,t-L]} \tilde{Q}_j \right)^+.
\]

To see why (2) (and hence, (3)) holds, observe that \( \left( D_{[s,t]} - \left( X_s + Q_s + \sum_{j \in [s,t-L]} u_j \right) \right)^+ > \tilde{Q}_j \) if and only if \( \left( D_{[s,t]} - \left( X_s + \sum_{j \in [s,t-L]} u_j \right) \right)^+ > 0 \). Next, we describe several properties of the parameters \( W_s \). Clearly, if \( \tilde{Q}_s = 0 \) (i.e., \( Q_s = u_s \)), then \( W_s = 0 \) for each \( t \geq s + L \). It is also readily verified from (3) that if \( W_s > 0 \) for some \( s \leq t - L \), then we have \( W_j = \tilde{Q}_j \) for each \( j \in (s, t - L) \).
For each \( s = 1 - L, \ldots, T - L \), let \( \tilde{\Pi}_t \) be the overall forced backlogging cost in periods \( s + L, \ldots, T \) associated with period \( s \), i.e., \( \tilde{\Pi}_t = \sum_{i=s+L}^{T} p_i W_{it} \) (we again assume that \( D_j = d_j \) with probability one for each \( j \leq 0 \)). Let \( u_{-L} = \infty, q_{-L} = 0 \), and \( \tilde{q}_{-L} = \infty \), and also define, for each \( t = 1, \ldots, T \),

\[
W_{-L,t} := \left( D_{t-L,t} - \left( x_{t-L} + \sum_{j=t-L+1}^{t-1} u_j \right) \right)^+ = \left( D_t - NI_t - \sum_{j=t-L+1}^{t-1} \tilde{q}_j \right)^+,
\]

and \( \tilde{\Pi}_{-L} := \sum_{j=1}^{T} p_j W_{-L,t} \). The last definition of \( \tilde{\Pi}_{-L} \) is meant to account for the forced backlogging cost, which is independent of any decision, and is forced by the demands on any feasible policy. It is now readily verified that, for each \( t = 1, \ldots, T \) and for each policy \( P \), we have \( \tilde{\Pi}_{-L} = p_t (D_t - NI_t^t) = p_t \sum_{i=t-L}^{T} W_{it} \) (the sum \( \sum_{i=t-L}^{T} W_{it} \) is telescopic). This implies the following theorem.

**Theorem 1.** Let \( P \) be a nonanticipatory policy. Then, the cost of policy \( P \) can be expressed as \( \mathcal{C}(P) := \sum_{t=1-L}^{0} \tilde{\Pi}_t + H_{(-\infty,T]} + \sum_{i=0}^{T} (H_i^P + \tilde{\Pi}_i) \).

Note that the first two terms of \( \mathcal{C}(P) \) in Theorem 1, \( \sum_{t=1-L}^{0} \tilde{\Pi}_t \) and \( H_{(-\infty,T]} \), are independent of any decision we make and are common to all feasible policies. Recall that \( \sum_{t=1-L}^{0} \tilde{\Pi}_t \) represents the forced backlogging penalty that is forced on any feasible policy. Because these two terms are also nonnegative, we omit them from the analysis. This does not impact our approximation results. From now on, we will write the cost of a feasible policy \( P \) as \( \mathcal{C}(P) = \sum_{l=1-L}^{0} (H_l^P + \tilde{\Pi}_l) \). In Online Appendix A, we provide an illustrative example of our new cost-accounting approach.

The intuition is that a shortage is incurred in period \( t \), it is allocated to past periods \( s < t - L \) in which the orders were below the available capacity. More specifically, the shortage and the resulting backlogging cost in period \( t \) are charged to periods \( s < t - L \) with positive unused slack capacity going backward in time from period \( t - L \). Each period \( s < t - L \) can be charged with part of the backlogging cost in period \( t \) up to \( \tilde{q}_s \) units, the unused slack capacity in period \( s \).

Figures 1, 2, and 3 graphically illustrate the difference between classical period-by-period accounting and forced marginal accounting for backlogging costs. All three figures reflect a single sample path of demands and orders. The total backlogging cost over the horizon is the area above the cumulative supply curve (thick line) and below the cumulative demand curve (thin line). Classical period-by-period accounting assigns to period \( s \) the difference between the curves at \( s \) (see Figure 1). Forced marginal accounting of backlogging costs assigns to period \( s \) all of the backlogging costs that were “forced,” or made inevitable, because we did not order to capacity in period \( s \). This corresponds to the area inside of the trapezoid shown in Figure 2. This trapezoid is created by extending the cumulative supply curve, starting at \( s - 1 \) and at \( s \), to the right at a slope equal to the capacity of the system. These lines represent what the supply curves would look like if our policy consistently ordered at full capacity from \( s - 1 \) and \( s \) onwards, respectively. In fact, consider the thick short bars in the trapezoid in Figure 2. The first and second terms of (2) are the vertical coordinates of the end points of these bars. Conse-
the distribution of the accumulated demand over the lead time, the computational effort involved with computing the marginal holding cost is of the same order of magnitude as for the myopic policy. Evaluating the marginal backlogging costs based on the scheme developed in this paper is analogous to the marginal holding cost. It is a sum of partial expectations of simple piecewise-linear functions, and therefore is no more difficult to compute.

Finally, observe that for uncapacitated models with \( u_s = \infty \) for each \( s \) (and hence \( q_s = \infty \)), our backlogging cost accounting is in fact identical to the traditional backlogging cost accounting discussed above. This implies that the cost-accounting scheme proposed in this paper is a generalization of the one introduced in Levi et al. (2007). Therefore, the preceding discussion is also a generalization of the corresponding algorithm and analysis in Levi et al. (2007).

4. Dual-Balancing Policy

In this section, we describe a new policy for the capacitated periodic-review stochastic inventory control problem. As in Levi et al. (2007), we call it a dual-balancing policy. We shall show that this policy has a worst-case performance guarantee of two, i.e., for each instance of the problem, the expected cost of the policy is at most twice the expected cost of an optimal policy. Recall the assumption discussed in §2, that the cost parameters imply no motivation for holding inventory or backorders. This implies that, without loss of generality, for each \( t = 1, \ldots, T \), \( c_t = 0 \) and \( h_t, p_t \geq 0 \). Moreover, we first describe the algorithm, its analysis, and several extensions under the latter assumption. Then in §4.2, we discuss in detail the generality of this assumption.

The dual-balancing policy presented in this paper is based on a balancing idea similar to the one used in Levi et al. (2007) for the uncapacitated model. That dual-balancing policy balances, in each period \( s \) and conditioned on the observed information set \( f_s \), the expected marginal holding cost of the units ordered in the period against the expected (traditional) backlogging cost in period \( s + L \), a lead time ahead of \( s \). However, it is readily seen that this approach does not work in the case where there is a capacity constraint on the size of the order in period \( s \). For one, the order size \( q_s \) that balances these two costs might not be reachable when \( q_s > u_s \).

In turn, we consider the forced marginal backlogging cost accounting and the corresponding cost it associates with period \( s \) as described in §3 above. Conditioned on the observed information set \( f_s \), we now balance the expected marginal holding cost of the units ordered in period \( s \) against the expected marginal backlogging costs associated with period \( s \). We will use the superscript \( B \) to refer to the dual-balancing policy. For each period \( s = 1, \ldots, T - L \), conditioning on the observed information set \( f_s \), let \( l^B_s(q_s) \) be the expected holding cost incurred over \( [s, T] \) by the units ordered by the dual-balancing policy in period \( s \). That is, \( l^B_s(q_s) := E[H^B_s(q_s) \mid f_s] \). In §3, we have defined \( H^B_s = \sum_j h_j (Q_s - (D_{t,j} - X^B_s)^+ \) (recall that we assume \( c_j = 0 \)). In addition, let \( \Pi^B_s := E[\Pi^B_s(q_s) \mid f_s] \) be the expected backlogging cost associated with period \( s \) by the forced marginal backlogging cost-accounting scheme described above, again conditioned on the observed information set \( f_s \). Recall that in §3 we have defined \( \Pi^B_s = \sum_j h_j W^B_{st} \), where

\[
W^B_{st} = \min \left\{ Q_s, \left( D_{[s,t]} - \left( X^B_s + Q_s + \sum_{j \in [s,t]} u_j \right)^+ \right) \right\}
\]

\[
= \left( D_{[s,t]} - \left( X^B_s + Q_s + \sum_{j \in [s,t-L]} u_j \right)^+ \right) - \left( D_{[s,t]} - \left( X^B_s + \sum_{j \in [s,t-L]} u_j \right)^+ \right).
\]

If we condition on \( f_s \), the inventory position at the beginning of period \( s \), \( x^B_s \), is known deterministically. That is, it is clear that \( l^B_s(q_s) \) and \( \Pi^B_s(q_s) \) are both indeed functions of \( q_s \), the number of units ordered in period \( s \).

We first discuss the case where the orders are allowed to be fractional. This implies that the functions \( l^B_s(q_s) \) and \( \Pi^B_s(q_s) \) are continuous. In each period \( s = 1, \ldots, T - L \), given the observed information set \( f_s \), the dual-balancing policy will order \( q_s^B = q_s \leq u_s \) units such that the expected marginal ordering and holding cost incurred by these units over \( [s, T] \) is equal to the expected forced marginal backlogging cost associated with period \( s \). In other words, we order \( q_s^B \) units such that \( l^B_s(q_s) = E[H^B_s(q_s) \mid f_s] = \Pi^B_s(q_s) = E[\Pi^B_s(q_s) \mid f_s] \). Next, we show that this policy is well defined. It is readily verified that \( l^B_s(q_s) \) is a convex increasing function of \( q_s \) that is equal to zero for \( q_s = 0 \) and goes to \( \infty \) as \( q_s \) goes to \( \infty \). Similarly,
one can verify that \( \overline{\pi}^B(q^B_t) \) is a decreasing convex function of \( q^B_t \) that has a nonnegative value at \( q^B_t = 0 \) and that is equal to zero for \( q^B_t = u_t \) (in this case there is no unused slack capacity at \( s \) and \( q^B_t = 0 \)). Our assumption that these functions are continuous implies that \( q^*_t \), as defined above, always exists.

Computationally, \( q^*_t \) is the minimizer of the function \( \gamma(q^B_t) := \max(I^B_t(q^B_t), \overline{\pi}^B(q^B_t)) \), which is a convex function of \( q^*_t \), because it is the maximum of two convex functions. Hence, in each period \( s \), we need to solve a convex minimization problem of a single variable. In particular, if for each \( j \geq s \), \( D_{[s,j]} \) is distributed according to any of those distributions that are commonly used in inventory theory, then it is extremely easy to evaluate the functions \( I^B_t(q^B_t) \) and \( \overline{\pi}^B(q^B_t) \). More generally, the complexity of the algorithm is of order \( T \) (i.e., number of time periods) times the complexity of solving the single variable convex minimization defined above. The complexity of this minimization problem can vary depending on the level of information we assume on the demand distributions and their characteristics. In all of the common scenarios, there exist straightforward methods to solve this problem efficiently.

In particular, \( q^*_t \) is determined by the intersection of two monotone convex functions, which suggests that bisection methods can be effective in computing \( q^*_t \). We note that the dual-balancing policy is not a state-dependent base-stock policy. However, it can be computed in an online manner, i.e., computing the policy action in period \( s \) does not require any knowledge of the future decisions to be made in the next periods. Moreover, unlike the myopic policy, the dual-balancing policy does use available information about long-term future demands.

### 4.1. Analysis

Next we show that, for each instance of the problem, the expected cost of the dual-balancing policy described above is at most twice the expected cost of an optimal policy. We will use the marginal cost-accounting scheme described in §3 and amortize the period cost of the dual-balancing policy with the cost of the optimal policy.

Using the marginal cost-accounting scheme discussed in §3, the expected cost of the dual-balancing policy can be expressed as \( E[\mathcal{C}(B)] = \sum_{t=1}^{T-L} E[H^B_t + \overline{\pi}^B] \). For each \( t = 1, \ldots, T-L \), let \( Z_t \) be the random balanced cost by the dual-balancing policy in period \( t \), i.e., \( Z_t = E[H^B_t | \mathcal{F}_t] \). Note that \( Z_t \) is a function of the observed information set in period \( t \). In the next lemma, we obtain an expression for the expected cost of the dual-balancing policy using the \( Z_t \) variables. The proof is identical to the proof of Lemma 4.1 in Levi et al. (2007).

**Lemma 1.** The expected cost of the dual-balancing policy is equal to twice the expected sum of the \( Z_t \) variables, i.e., \( E[\mathcal{C}(B)] = 2 \sum_{t=1}^{T-L} E[Z_t] \).

In the next two lemmas, we show that the cost of OPT can be amortized against some of the cost of the dual-balancing policy. In particular, they imply that the expected cost of OPT is at least \( \sum_{t=1}^{T-L} E[Z_t] \). For each realization of the demands \( D_t, \ldots, D_T \), let \( \mathcal{F}_t \) be the set of periods \( t = 1, \ldots, T-L \) in which the optimal policy had inventory position higher than that of the dual-balancing policy, i.e., the set of periods \( 1 \leq t \leq T-L \) such that \( Y^B_t < Y^\text{OPT}_t \). Let \( \mathcal{F}_1 \) be the set of periods in which the dual-balancing had inventory position at least as high as that of OPT, i.e., the set of periods \( t = 1, \ldots, T-L \) such that \( Y^B_t \geq Y^\text{OPT}_t \). (We consider only the periods \( t = 1, \ldots, T-L \) because the effective ordering decisions are made in these periods. Specifically, each order placed after period \( T-L \) will arrive after period \( T \).) Observe that \( \mathcal{F}_t \) and \( \mathcal{F}_1 \) are random sets that induce a random partition of the horizon.

The next lemma shows that, with probability one, the marginal holding cost incurred by the dual-balancing policy in periods \( t \in \mathcal{F}_1 \) is at most the total holding cost incurred by OPT, denoted by \( H^\text{OPT} \), i.e., \( \sum_{t \in \mathcal{F}_1} H^B_t \leq H^\text{OPT} \) with probability one. The proof is identical to the proof of Lemma 4.2 in Levi et al. (2007).

**Lemma 2.** For each realization \( f_t \in \mathcal{F}_1 \), the total marginal holding cost incurred by the dual-balancing policy for all of the periods \( t \in \mathcal{F}_1 \) is at most the total holding cost incurred by OPT, denoted by \( H^\text{OPT} \), i.e., \( \sum_{t \in \mathcal{F}_1} H^B_t \leq H^\text{OPT} \) with probability one.

The next lemma shows that, with probability one, the marginal backlogging cost of the dual-balancing policy associated with periods \( t \in \mathcal{F}_1 \) is at most the total backlogging penalty incurred by OPT, denoted by \( \Pi^\text{OPT} \).

**Lemma 3.** For each realization \( f_t \in \mathcal{F}_1 \), the total marginal backlogging cost of the dual-balancing policy associated with all of the periods \( t \in \mathcal{F}_1 \) is at most the total backlogging penalty incurred by OPT, denoted by \( \Pi^\text{OPT} \), i.e., \( \sum_{t \in \mathcal{F}_1} \Pi^B_t \leq \Pi^\text{OPT} \) with probability one.

The forced marginal backlogging cost associated with the periods in \( \mathcal{F}_1 \) is equal to

\[
\sum_{t \in \mathcal{F}_1} \sum_{s=t-L+1}^{t+1} p_s W^B_s = \sum_{t \in \mathcal{F}_1} \sum_{s=t-L}^{t+1} W^B_s.
\]

Therefore, it is sufficient to show that for each \( t = L+1, \ldots, T \), the traditional backlogging cost incurred by OPT in that period is at least as much as the forced backlogging costs incurred by the dual-balancing policy in period \( t \) as a result of decisions made in periods \( \{s \in \mathcal{F}_1: s \leq t-L\} \). In other words, it is sufficient to show that for each \( t = L+1, \ldots, T \), we have

\[
(D_t - N^\text{OPT}_t^*) \geq \sum_{s \in \mathcal{F}_1: s \leq t-L} W^B_s,
\]

with probability one. (Recall that the backlogging costs over the periods \( 1, \ldots, L \) are the same for all policies.)
Consider now a specific realization \( f_t \in \mathcal{F}_T \) and some period \( t = 1, \ldots, T \). If there is no period in \( \{ s \in \mathcal{F}_H : s \leq t - L \} \) with \( w^b_s > 0 \), then there is nothing to prove. Assume that such a period \( s \) exists, and let \( s_t \) and \( s_e \) be the latest and the earliest periods in the set \( \{ s \in \mathcal{F}_H : s \leq t - L, w^b_s > 0 \} \), respectively (it is possible that \( s_t = s_e \)). We note again that here we abuse our notation and consider the set \( \mathcal{F}_H \) as the realized set of periods according to the specific realization \( f_t \). In particular, \( s_t \) and \( s_e \) are the respective realizations of random variables \( S_t \) and \( S_e \). We have already seen (in the discussion in §3) that for each \( s \in \{ s_t, s_e \} \), we have \( w^b_s = \tilde{d}^b_t \) and \( w^b_{s_t, t} = d_{[s_t, t]} - (x_t + q^b_t + \sum_{j \in (s_t, \ldots, t]} u_j) \). Indeed,

\[
d_t - m^\text{OPT}_t = d_t - \left( y^\text{OPT}_t + \sum_{j \in (s_t, \ldots, t]} q^\text{OPT}_j - d_{[s_t, t]} \right) \\
\geq d_{[s_t, t]} - \left( y^b_t + \sum_{j \in (s_t, \ldots, t]} u_j \right) \\
= d_{[s_t, t]} - \left( y^b_t + \sum_{j \in (s_t, s_e]} q^b_j - d_{[s_t, s_e]} + \sum_{j \in (s_t, \ldots, t]} u_j \right) \\
= d_{[s_t, t]} - \left( x_t + q^b_t + \sum_{j \in (s_t, \ldots, t]} u_j \right) + \sum_{j \in (s_t, s_e]} \tilde{d}^b_j \\
\geq \sum_{j \in (s_t, s_e]} w^b_j \geq \sum_{j \in (s_t, s_e]} w^b_{s_j}.
\]

The first equality is again based on the fact that for each feasible policy and for each \( s \leq t \), we have \( N_s = Y_s + \sum_{j \in (s, \ldots, t]} Q_j - D_{[s, t]} \), applied to OPT and periods \( s_t \leq t - L \). The first inequality follows from the assumption that \( s_t \in \mathcal{F}_H \) and so \( y^\text{OPT}_t \leq y^b_t \), and from the capacity constraints that imply \( q^\text{OPT}_j \leq u_j \). The second equality follows from the fact that (for each \( s \leq s' \)) \( Y_s = Y_s + \sum_{j \in (s, \ldots, s']} Q_j - D_{[s, \ldots, s']} \) applied to the dual-balancing policy and periods \( s_s \leq s_t \). The last equality is achieved by adding and subtracting \( \sum_{j \in (s_t, s_e]} \tilde{d}^b_j \) and from the fact that \( u_j = Q_j + \tilde{Q}_j \). The proof then follows.

As a corollary of Lemmas 1, 2, and 3, we get the following theorem.

**Theorem 2.** The dual-balancing policy has a worst-case performance guarantee of two, i.e., for each instance of the capacitated periodic-review stochastic inventory control problem, the expected cost of the dual-balancing policy is at most twice the expected cost of an optimal solution, i.e., \( \mathbb{E}[\mathcal{E}(B)] \leq 2 \mathbb{E}[\mathcal{E}(\text{OPT})] \).

From Lemma 1, we know that the expected cost of the dual-balancing policy is equal to twice the expected cost of the sum of the \( Z_t \) variables, i.e., \( \mathbb{E}[\mathcal{E}(B)] = \sum_{t=1}^{T-L} \mathbb{E}[Z_t] \).

From Lemmas 2 and 3 we know that, with probability one, the cost of OPT is at least as much as the holding cost incurred by units ordered by the dual-balancing policy in periods \( t \in \mathcal{F}_H \) plus the forced marginal backlogging cost of the dual-balancing policy that is associated with periods \( t \in \mathcal{F}_H \). In other words, with probability one, \( H^\text{OPT} + \bar{H}^\text{OPT} \geq \sum_{t \in \mathcal{F}_H} H^b_t + \sum_{t \in \mathcal{F}_H} \bar{H}^b_t \). Again using conditional expectations and the definition of \( Z_t \), this implies that indeed,

\[
\mathbb{E}[\mathcal{E}(\text{OPT})] \\
\geq \mathbb{E}\left[ \sum_{t} \left( H^b_t + \bar{H}^b_t \right) \right] \\
= \sum_{t} \mathbb{E}[H^b_t \cdot \mathbb{1}(t \in \mathcal{F}_H) + \bar{H}^b_t \cdot \mathbb{1}(t \in \mathcal{F}_H)] \\
= \sum_{t} \mathbb{E}[\mathbb{E}[H^b_t \cdot \mathbb{1}(t \in \mathcal{F}_H) + \bar{H}^b_t \cdot \mathbb{1}(t \in \mathcal{F}_H) | \mathcal{F}_H]] \\
= \sum_{t} \mathbb{E}[[\mathbb{1}(t \in \mathcal{F}_H) + \mathbb{1}(t \in \mathcal{F}_H)) Z_t] = \sum_{t} \mathbb{E}[Z_t].
\]

We note that if the optimal policy is deterministic (i.e., it makes deterministic decisions in each period \( t \) given the observed information set \( f_t \)), then if we condition on \( \mathcal{F}_H \), then \( y^b_t \) and \( y^\text{OPT}_t \) are known deterministically, and so are the indicators \( \mathbb{1}(t \in \mathcal{F}_H) \) and \( \mathbb{1}(t \in \mathcal{F}_H) \). If the optimal policy is random, then the same arguments above still work. We now need to condition not only on \( \mathcal{F}_H \), but also on the decisions made by the policies. Because the inventory control policy does not have any effect on the evolution of the demand, the arguments above are still valid. This concludes the proof of the theorem.

We note that the examples discussed in Levi et al. (2007) show that the above analysis is tight. However, the analysis hints that in a typical scenario, the performance would be significantly better. Hurley et al. (2006) present a thorough empirical analysis of the typical performance of dual-balancing policies in uncapacitated models. In §6, we present empirical results that confirm that this phenomenon extends to the capacitated case.

Finally, we note that the dual-balancing policies and the worst-case analysis can be extended to models where the capacities in each period are generated by some exogenous random process, and the exact capacity available in period \( t \) is observed only at the beginning of the period. Thus, the dual-balancing policies provide a worst-case guarantee of two for this important extension as well. In this case, the expectations of the marginal backlogging costs are taken with respect to both the random future demands and random future capacities. In Online Appendix C, we consider two extensions of the dual-balancing policy and the worst-case analysis. Specifically, we discuss the extensions to models where orders must be integral and the demands are integer-valued random variables, and to models with stochastic lead times under the no-order-crossing assumption.

### 4.2. Cost Transformation

In this section, we discuss in detail the cost transformation that enables us to assume, without loss of generality, that
for each period $t = 1, \ldots, T$, we have $c_t = 0$ and $h_t, p_t \geq 0$. Consider any instance of the problem with cost parameters that imply no speculative motivation for holding inventory or backorders (as discussed in §2). Following Levi et al. (2007), we use a simple transformation of the cost parameters to construct an equivalent instance, with the property that for each period $t = 1, \ldots, T$, we have $c_t = 0$ and $h_t, p_t \geq 0$. More specifically, the modified instance has the same set of optimal policies. Applying the dual-balancing policy to that instance, we obtain a policy that is different from the original dual-balancing policy, and which also has a performance guarantee of at most two with respect to the original problem. We shall show that this cost transformation can improve the performance guarantee of the dual-balancing policy in cases where the ordering cost is the dominant part of the overall cost. In practice, this is often the case.

We now describe the transformation for the case with no lead time ($L = 0$) and $\alpha = 1$; the extension to the case of arbitrary lead time is straightforward. Recall that any feasible policy $P$ satisfies, for each $t = 1, \ldots, T$, $Q_t := NI_t - NI_{t-1} + D_t$ (for ease of notation, we omit the superscript $P$). Using these equations, we can express the ordering cost in each period $t$ as $c_t(NI_t - NI_{t-1} + D_t)$. Now replace $NI_t$ with $NI_t^+ - NI_t^-$, its respective positive and negative parts.

This leads to the following transformation of cost parameters. We let $\hat{c}_t := 0$, $\hat{h}_t := h_t + c_t - c_{t+1}(c_{t+1} = 0)$, and $\hat{p}_t := p_t - c_t + c_{t+1}$. Note that the assumptions on the cost parameters $c_t$, $h_t$, and $p_t$ discussed in §2, and in particular the assumption that there is no speculative motivation to hold inventory or backorders, imply that $\hat{h}_t$ and $\hat{p}_t$ above are nonnegative ($t = 1, \ldots, T$). Observe that the parameters $\hat{h}_t$ and $\hat{p}_t$ will still be nonnegative even if the parameters $c_t$, $h_t$, and $p_t$ are negative and as long as the above assumption holds. Moreover, this enables us to incorporate into the model a negative salvage cost at the end of the planning horizon (after the cost transformation we will have nonnegative cost parameters). It is readily verified that the induced problem is equivalent to the original one. More specifically, for each realization of the demands, the cost of each feasible policy $P$ in the modified input decreases by exactly $\sum_{t=1}^{T} c_t d_t$ (compared to its cost in the original input). Therefore, any optimal policy for the modified input is also optimal for the original input.

Now apply the dual-balancing policy to the modified problem. We have seen that the assumptions on $c_t$, $h_t$, and $p_t$ ensure that $\hat{h}_t$ and $\hat{p}_t$ are nonnegative, and hence the analysis presented above is valid. Let opt and opt be the optimal expected cost of the original and modified inputs, respectively. Clearly, opt = opt + E[\sum_{t=1}^{T} c_t D_t]. Now the expected cost of the dual-balancing policy in the modified input is at most 2opt. Its cost in the original input is then at most 2opt + E[\sum_{t=1}^{T} c_t D_t] = 2opt - E[\sum_{t=1}^{T} c_t D_t]. This implies that if E[\sum_{t=1}^{T} c_t D_t] is a large fraction of opt, then the performance guarantee of the expected cost of the dual-balancing policy might be significantly better than two.

For example, if $E[\sum_{t=1}^{T} c_t D_t] \geq 0.5 opt$, then we can conclude that the expected cost of the dual-balancing policy is at most 1.5 opt. It is indeed the case in many real-life problems that a major fraction of the total cost is due to the ordering cost. The intuition of the above transformation is that $\sum_{t=1}^{T} c_t D_t$ is a cost that any feasible policy must pay. As a result, we treat it as an invariant in the cost of any policy and apply the approximation algorithm to the rest of the cost.

In the case where we have a lead time $L$, we use the equations $Q_t := NI_{t+L} - NI_{t+L-1} + D_{t+L}$, for each $t = 1, \ldots, T - L$, to get the same cost transformation. The transformation for $\alpha > 1$ is also straightforward. Also, it is not hard to see that the cost transformation can be modified to remove, say, $\gamma$% of the per-unit ordering costs, where $0 < \gamma < 100$. This leads to a continuum of dual-balancing policies, all of which are two-approximations.

5. Improved Policy and Bounds on the Optimal Inventory Levels

In this section, we consider two semimyopic (modified) base-stock policies that are easy to compute in an online manner and provide, respectively, lower and upper bounds on the inventory levels of an optimal policy $\gamma^O_{T}$, in each period $t = 1, \ldots, T$. We believe that these bounds can be used effectively to improve existing algorithms for computing inventory control policies for the capacitated model discussed in this paper and other capacitated stochastic inventory models. Moreover, as in Hurley et al. (2006), we shall show that these policies provide bounds that are strong in the following sense: each policy that for some period $t$ and some state $s$, has inventory level outside the range defined by the respective lower and upper bounds can be improved. In particular, there is another (modified) policy that in period $t$ and state $s$, admits an inventory level within the specified range, with expected cost no greater than the expected cost of the original policy. In other words, any policy that violates these respective bounds is dominated by another policy. We then follow Hurley et al. (2006) and construct an "improved dual-balancing policy" that incorporates these bounds. This policy also has a performance guarantee of two, and as the computational study for the uncapacitated model in Hurley et al. (2006) suggests, we expect that it will have a better typical performance.

The policies we consider are called lower-myopic (denoted by LM) and upper-myopic (denoted by UM), respectively. In the lower-myopic policy, in each period $s$, conditioning on the observed information set $f_s$, we minimize the sum of the expected marginal holding cost of the units ordered in that period and the traditional expected backlogging costs a lead time ahead. That is, in each period $s$, we minimize

$$g^L_M(q_s) = \min_{q_s} \{ \text{opt} + E[p_{s+1}D_{t,s+1} + (x_s + q_s) \gamma_s] | f_s \}$$
under the constraint $q_s \leq u_s$. This is a convex function of $q_s$. This policy was first proposed for the uncapacitated model by Levi et al. (2007), who called it the minimizing policy. They have shown that this is a base-stock policy that provides lower bounds on the optimal base-stock levels. However, in the capacitated model it is possible that the actual minimizer will not be attainable. In this case, we order up to capacity, and this provides a modified base-stock policy. In this paper, we extend and generalize their proof for the capacitated model. In the upper-myopic policy, in each period $s$, again conditioning on $f_s$, we minimize the sum of the expected period holding cost and the expected forced marginal backlogging. Thus, we minimize

$$g_s^{UM}(q_s) = \bar{\pi}_s^{UM}(q_s) + \mathbb{E}\left[b_{s+L}(x_s + q_s - D_{[1, \ldots, t]})^+ | f_s\right],$$

subject to $0 \leq q_s \leq u_s$, which is also convex in $q_s$. We shall show that this policy provides upper bounds on the inventory levels of an optimal policy. By arguments similar to the ones used by Levi et al. (2007), it can be shown that this gives rise to yet another modified base-stock policy. (In particular, $g_s^{UM}(q^1) - g_s^{UM}(q^2)$ depends only on $y^1 = x_s + q^1$ and $y^2 = x_s + q^2$.) To the best of our knowledge, this is a new way for deriving upper bounds on the inventory levels of an optimal policy in the capacitated model. We note that it is not clear whether the classical myopic policy, where we minimize the expected period cost, provides any bounds for capacitated models. Another similar question is how the policy that, in each period, minimizes the sum of the expected marginal holding marginal cost and expected forced marginal backlogging cost is related to an optimal policy.

Let $Y_s^{LM}$ and $Y_s^{UM}$ be the respective inventory position (after orders are placed) of the lower-myopic and the upper-myopic policies in period $t = 1, \ldots, T$. Specifically, we assume that $Y_s^{LM}$ is the smallest minimizer of the corresponding period problem being solved (see above), and that $Y_s^{UM}$ is the largest minimizer of the corresponding period problem. Note that the inventory position levels depend on the specific state ($f_s, x_s$), but for ease of notation we omit the indication of the state. The two semimyopic policies described above can be implemented in an online manner, i.e., regardless of the action control in future periods. We shall show that for each evolution $f_T$, these two policies provide lower and upper bounds on the inventory levels of any optimal policy, i.e., $Y_s^{LM} \leq Y_s^{OPT} \leq Y_s^{UM}$, with probability one, for each $t = 1, \ldots, T$. Moreover, we shall show that each non-dominated policy $P$ must have $Y_s^{LM} \leq Y_s^P \leq Y_s^{UM}$ for each $t = 1, \ldots, T$.

The next two lemmas show that each policy $P$ that has, for some period $s$ and state $f_s$, inventory position $y^s \notin [y_s^{LM}, y_s^{UM}]$, can be strictly improved by a modified policy $P'$ with $y^s \in [y_s^{UM}, y_s^{LM}]$ and expected cost at most the expected cost of $P$. For the sake of simplicity, we consider a model with no lead time (the extensions to the case with $L > 0$ are straightforward).

**Lemma 4.** Consider a feasible policy $P$, and suppose that for some period $s$ and information set $f_s$, we have $y^s < y_s^{LM}$. Further assume that $s$ is the earliest such period. Then, the policy $P'$ that follows $P$ until period $s - 1$, then orders up to $y_s^{LM}$ in period $s$ and again imitates $P$ over the interval $(s, T]$, has expected cost no larger than the expected cost of $P$.

Because $P'$ follows $P$ over $[1, s)$, we conclude that they incur exactly the same cost over that interval, and that they have the same inventory position $x_s \leq y^s < y_s^{LM}$. Because $s$ is the first such period, we conclude that $P'$ can indeed order up to $y_s^{LM}$. Now over $(s, T]$, $P'$ imitates $P$, that is, it orders nothing if $X_s^j \geq y^s$ and orders up to $y_s^P$ otherwise (for each $j \in (s, T]$). Moreover, the policy $P'$ has ordered $q^P_s$ units in period $s$. Consider the overall expected marginal holding cost of these units and the expected (traditional) backlogging cost incurred by $P'$ in period $s$. By the definition of $q^P_s$, it is clear that this is no greater than the expected marginal holding cost and expected (traditional) backlogging cost incurred by the policy $P$ in period $s$. For each period $j \in (s, T]$, we know that with probability one, $Y^P_j \geq y^s$ and that $Q^P_j \leq Q^P_j$. This implies that the backlogging incurred by policy $P'$ over that interval is no greater than the backlogging cost incurred by policy $P$, and similarly, the marginal holding-cost policy that $P'$ incurs over that interval is no greater than the respective marginal holding cost of policy $P$. The lemma then follows.

**Lemma 5.** Consider a feasible policy $P$, and suppose that for some period $s$ and information set $f_s$, we have $y^s > y_s^{UM}$. Further assume that $s$ is the earliest such period. Then, the policy $P'$ that follows $P$ until period $s - 1$, then orders up to $y_s^{UM}$ in period $s$ and again imitates $P$ over the interval $(s, T]$, has expected cost no larger than the expected cost of $P$.

By arguments identical to the ones in Lemma 4, we conclude that $P'$ and $P$ incur the same cost over $[1, s)$ and that they have the same inventory position $x_s \leq y_s^{UM} < y^s$. The first inequality follows from the fact that $s$ is the first period in which $P$ has more inventory than the upper-myopic policy. Thus, $P'$ can order up to $y_s^{UM}$, and assume that it orders $q^P_s$. Consider the overall expected forced marginal backlogging cost and expected period holding cost incurred in period $s$ by policy $P'$. By the definition of $q^P_s$, we conclude that this expected cost is smaller than the respective expected cost incurred by policy $P$ in period $s$. Now over $(s, T]$ $P'$ again tries to imitate $P$, i.e., for each $j \in (s, T]$, it will order up to $y^s$ or up to the capacity $u_j$. Now let $S'$ be the earliest (random) period after period $s$ in which $P'$ has reached $y^s$. Clearly, over $(S', T]$ the policies $P'$ and $P$ are again identical, and hence incur the same cost. Observe that for each $j \in (S', T]$, we have $Y^P_j \leq y^s$ and $Q^P_j \leq Q^P_j$, with probability one. This implies that the expected holding cost and the expected forced marginal backlogging penalty incurred by policy $P'$ over that interval are each no greater...
than the respective expected cost incurred by policy P. The lemma then follows.

Lemma 4 and 5 imply the following corollary.

**Corollary 1.** For any optimal policy and for each complete evolution \( f_s \), the lower-myopic and upper-myopic policies provide respective lower and upper bounds on the inventory levels of the optimal policy, i.e., \( Y_s^{LM} \leq Y_s^{OPT} \leq Y_s^{UM} \) with probability one for each \( t = 1, \ldots, T \).

Now consider the improved dual-balancing policy denoted by superscript IB. In each period \( s \), given the observed information set \( f_s \), and the inventory position at the beginning of the period, we still consider balancing the expected marginal holding cost against the expected marginal backlogging cost, and compute \( q'_t \) as described in §4. (That is, given the observed information set \( f_s \), and the inventory position at the beginning of period \( s \), ordering \( q'_t \) will balance the expected marginal holding cost and the expected marginal forced backlogging costs associated with period \( s \).) However, in each case where the original balancing quantity brings the inventory position below \( y_s^{LM} \) (i.e., \( x^{IB}_t + q'_t < y_s^{LM} \)) or above \( y_s^{UM} \) (i.e., \( x^{IB}_t + q'_t > y_s^{UM} \)), we fix this decision by instead increasing the order up to \( y_s^{LM} \) or decreasing it down to \( y_s^{UM} \), respectively. It can be readily verified that for each evolution \( f_s \) and each period \( s \), we have \( y_s^{LM} \leq y_t^{LM} \leq y_t^{UM} \leq y_s^{UM} \).

We next prove the following theorem.

**Theorem 3.** The improved dual-balancing policy has a performance guarantee of two.

Observe that in the improved dual-balancing policy it is no longer true that in each period \( t \), the expected marginal holding cost is equal to the expected forced marginal backlogging cost. Now let \( Z_t \) be the maximum among the expected marginal holding cost and expected forced marginal backlogging cost, i.e., \( Z_t = \max \{ E[H_t^{IB}(Q_t)] \mid \mathcal{F}_t \} \), \( E[\Pi_t^{IB}(Q_t) \mid \mathcal{F}_t] \}, \) where \( Q_t^{IB} \) is the order quantity placed by the improved dual-balancing policy in period \( s \). As already mentioned, \( Q_t^{IB} \) can be either larger or smaller than the balancing quantity \( Q_t^{IB} \). Similar to Lemma 1, we now conclude that \( E[\epsilon(IB)] \leq 2 \sum_t E[Z_t] \).

Next, we modify the definition of the sets \( \mathcal{F}_H \) and \( \mathcal{F}_H \) in §4. The set \( \mathcal{F}_H \) will consist of periods \( t = 1, \ldots, T - L \) such that (i) \( Y^{LM}_t < Y^{IB}_t < Y^{UM}_t \) and \( Y^{IB}_t \leq Y^{OPT}_t \); or (ii) \( Y^{IB}_t = Y^{LM}_t < Y^{UM}_t \), or (iii) \( Y^{IB}_t = Y^{LM}_t = Y^{UM}_t = Y^{OPT}_t \), and the improved dual-balancing policy orders more than the balancing quantity \( Q_t^{IB} \). (That is, \( x^{IB}_t + Q_t^{IB} > y^{LM}_t \) and \( Q_t^{IB} > Q_t^{IB} \).) The set \( \mathcal{F}_H \) will consist of all the other periods in \( t = 1, \ldots, T - L \). Specifically, \( \mathcal{F}_H \) contains periods such that (i) \( Y^{LM}_t < Y^{IB}_t < Y^{UM}_t \) and \( Y^{IB}_t > Y^{OPT}_t \); or (ii) \( Y^{LM}_t < Y^{IB}_t = Y^{UM}_t \), or (iii) \( Y^{IB}_t = Y^{LM}_t = Y^{UM}_t = Y^{OPT}_t \), and the improved dual-balancing policy orders less than the balancing quantity \( Q_t^{IB} \). (That is, \( x^{IB}_t + Q_t^{IB} < y^{LM}_t \) and \( Q_t^{IB} < Q_t^{IB} \).) Note that for each \( t \in \mathcal{F}_H \), we have \( Y^{IB}_t \leq Y^{OPT}_t \) and for each \( t \in \mathcal{F}_H \), we have \( Y^{IB}_t > Y^{OPT}_t \). Thus, the arguments used to prove Lemmas 2 and 3 are still valid. It is then sufficient to show that for each \( t \in \mathcal{F}_H \), we have \( E[H_t^{IB}(Q_t^{IB})] \mid \mathcal{F}_t] = Z_t \), and for each \( t \in \mathcal{F}_H \), we have \( E[\Pi_t^{IB}(Q_t^{IB})] \mid \mathcal{F}_t] = Z_t \). This will imply that the arguments in the proof of Theorem 2 are still valid and the performance guarantee of the policy then follows.

Assume now that for some \( f_s \in \mathcal{F}_H \), such that \( t \in \mathcal{F}_H \), we have \( E[H_t^{IB}(Q_t^{IB})] \mid \mathcal{F}_t] < z_t \). However, this can happen only if in that period the improved dual-balancing policy orders \( Q_t^{IB} \) and \( Y^{IB}_t = Y^{UM}_t \). (The improved dual-balancing policy orders \( Q_t^{IB} < Q_t^{IB} \) only when \( X^{IB}_t + Q_t^{IB} > Y^{UM}_t \), and then it decreases the order until \( Y^{IB}_t = Y^{UM}_t \).) This leads to a contradiction because by definition \( t \in \mathcal{F}_H \) (see cases (ii) and (iii) in the definition of \( \mathcal{F}_H \) above).

Similarly, assume that for some \( f_s \in \mathcal{F}_H \), such that \( t \in \mathcal{F}_H \), we have \( E[H_t^{IB}(Q_t^{IB})] \mid \mathcal{F}_t] > z_t \). This can happen only if in that period the improved dual-balancing policy orders \( Q_t^{IB} > Q_t^{IB} \) (i.e., \( X^{IB}_t + Q_t^{IB} < Y^{LM}_t \)) and \( Y^{IB}_t = Y^{UM}_t \). However, we again get a contradiction because by definition \( t \in \mathcal{F}_H \) (see cases (ii) and (iii) in the definition of \( \mathcal{F}_H \) above). This concludes the proof of the lemma.

6. Computational Experiments

As we mentioned in the introduction, due to state space explosion, the corresponding inventory control models are very difficult from a computational perspective. Consequently, we study the typical performance of the balancing policies in two settings. In the first setting, the optimal solution of the capacitated inventory system is easily computed, but there is no evolution of forecasts (i.e., demands are independent over time). This enables us to see how close to optimal the balancing policy is in at least one setting. The second experiment is more realistic, in that the demand and forecast evolution processes are governed by the multiplicative MMFE model. In fact, these are the settings in which balancing policies are most attractive because optimal policies are inaccessible and no provably good heuristics or even reasonable lower bounds are available. As a result, we benchmark the performance of the balancing policies using the myopic and the other semimyopic policies developed in this paper in §5. In these experiments, the balancing policies were very robust. For the model with independent demands, the dual-balancing policy came within 11% of the optimal cost on average, within 17% of optimal in 95% of the trials, and never exceeded the optimal cost by more than 25%. Moreover, the balancing policies outperform the myopic policy by 49% in the first experiment and by 27% in the second, on average. (In many scenarios, the balancing policies improve upon myopic by more than 50%.) This indicates that the typical performance of the balancing policies is significantly better than the worst-case guarantees.

6.1. Experiments with Translated-Mass Exponential Demand Distributions

In this experiment, we consider infinite-horizon problems with i.i.d. demand, i.e., the distribution of \( (D_t \mid \mathcal{F}_t) \)
Figure 4. Sensitivity of performance to capacity, backorder costs, and demand variance.

Figure 5. Histogram of cost, as a fraction of optimal cost.

In addition, we randomly generated 1,000 problem instances, using a mean demand of one. The capacity, the backorder-to-holding-cost ratio, and the standard deviation of the demand are all randomly generated from translated beta distributions. For the capacity, the distribution has minimum, maximum, mean, and standard deviation equal to (1.05, 3.3, 1.61, 0.32). For the backorder-to-holding-cost ratio and the standard deviation of the demand, the corresponding values are (1, 101, 26.00, 14.43) and (0.1, 3.6, 0.98, 0.51). The computations were done using JAVA on a standard PC, and computing the balancing decision in each period took 0.00015 seconds on average.

Figure 5 shows histograms of the ratio of the balancing policy’s cost and the optimal cost, and the ratio of the myopic policy’s cost and the optimal cost. Figure 6 is a restricted view of Figure 5, with a finer grid, limited to the neighborhood around one. The ratio of the balancing policy’s cost to the optimal cost is 1.11 on average, with a standard deviation of 0.049, a 95th percentile of 1.17, and a maximum of 1.58. For the myopic, the corresponding ratio has mean 1.60, standard deviation 0.92, 95th percentile 3.38, and maximum 8.61. This indicates that the

is independent of both $\mathcal{F}_t$ and $t$. We assume that $D_t$ has a translated-mass exponential distribution, meaning that $P(D_t > x) = 1$ if $x < a$, and otherwise, $P(D_t > x) = q e^{-\theta(x-a)}$, where $0 \leq q \leq 1$, $\theta > 0$, $a \geq 0$, and $a \cdot (1 - q) = 0$. If $q = 1$, then $D_t$ has an exponential distribution, translated to the right by $a$ units. If $q < 1$, then $a = 0$, $D_t = 0$ with probability $1 - q$, and with probability $q$, $D_t$ follows an exponential distribution. For every positive mean and variance, there is a unique translated-mass exponential distribution.

For infinite-horizon problems with translated-mass exponential demand, a stationary order-up-to policy is optimal. The optimal policy and its cost are easily obtained, using the following observation: for translated-mass exponential demand, the lower and upper bounds in Theorem 2 of Glasserman (1997) coincide.

The demand $D_t$ has mean one. We start with a base case, in which $D_t$ has variance one, the capacity is 1.5, and the backorder cost per day is eight times larger than the holding cost. Figure 4 illustrates what happens when we fix two of these parameters and vary the third one. On the vertical axis we show the ratio of the cost of the balancing policy to the optimal cost, and the ratio of the myopic cost to the optimal cost. Note that the scale on the vertical axis is not uniform. For the solid lines, the horizontal axis displays the excess capacity (i.e., the capacity minus the mean demand, or “capacity − 1”). For the dashed lines, the horizontal ordinate is the ratio of the backorder cost per day to the holding cost. For the dotted lines, the horizontal ordinate is the variance of the demand.
balancing policy is very robust compared to the myopic policy.

6.2. Experiments with Multiplicative-MMFE-Based Demand and Forecast Evolution

This test uses the experimental design of Hurley et al. (2006), in which the uncapacitated version of the balancing algorithm was tested. In all of our experiments, the holding and backorder costs are $h_i = 1$ and $p_i = 10$. A horizon of length $T = 40$ was used, and forecasts of demand evolve according to the multiplicative MMFE model (Graves et al. 1986, Heath and Jackson 1994). The mean demand per period, averaged over the 40 periods in the time horizon, is 400 in all cases. The capacity is 460 units per period.

The experimental design consists of 82 scenarios. For each scenario, we tested 1,000 random problem instances. The scenarios were designed to capture a variety of settings and characteristics. Demand and forecast variability can be either high or low, and lead times can be short or long. Some scenarios study different types of seasonality in the demand. Others consider product launches and product phaseouts. Some scenarios account for the fact that many forecasting systems generate accurate forecasts that extend many time periods into the future, whereas other systems can only forecast accurately in the near term. In addition, shifts in forecasts can demonstrate either no correlation, positive correlation, or negative correlation. The scenarios are described in detail in Online Appendix B and in Hurley et al. (2006).

We study five policies: myopic, lower myopic, upper myopic, dual-balancing, and improved balancing. For each of the 82 scenarios constructed and for each policy, we examine the average per-period cost of the policy over 1,000 runs. Note that because we consider a complex environment and relatively long horizon ($T = 40$), it is not possible to compute the optimal expected cost. Moreover, to the best of our knowledge, it is not even known how to compute reasonable lower bounds in this setting. Instead, we use as our benchmark the myopic policy and the other semimyopic policies discussed in §5. The policies were computed using MATLAB on a standard PC. The average times to compute the period ordering decisions were $0.0031, 0.0738, 0.0412$ seconds for the myopic, the minimizing, and balancing policies, respectively.

In Figure 7, we provide histograms of the ratio of the cost of each policy, divided by the cost of myopic. Both dual-balancing and improved balancing outperform myopic in every one of the 82 scenarios. Relative to myopic, they provide an average saving of 27.2% and 32.4%, respectively. Lower myopic is very close to myopic (the ratio is usually close to one), and is sometimes worse than myopic. The trend is not unexpected because myopic often underorders in capacitated systems, and lower myopic always orders less than myopic. Upper myopic is virtually identical to improved dual-balancing, which truncates the balancing order quantities using the order-up-to levels of upper and lower myopic.

In all of our computational experiments, the performance of the balancing policy is both strong and consistent. Improved balancing is better than balancing.

7. Electronic Companion

An electronic companion to this paper is available as part of the online version that can be found at http://or.journal.informs.org/.
